

# Generalization and Cost Function

## Intuition from Last Exercise

- Perceptron is just having a straight line and assign everything above to one. class and everything below to another class.
- The math is simple  $h(x) = \text{sign}(\mathbf{w}^T \mathbf{x})$ . Don't forget to pad the  $\mathbf{x}$ .
- The line is defined by the relation  $\mathbf{w}^T \mathbf{x} = 0$ . What do you expect the boundary that separate positive and negative, it must be zero.
- The learning algorithm is there to pick the "best" line.
- The more training data you have the more chance that your  $E_{\text{out}}$  will match  $E_{\text{in}}$ . We hope that our hypothesis will "generalize"  $E_{\text{in}} = E_{\text{out}}$ .
- The less complicated your model is the more chance that your  $E_{\text{out}}$  will match  $E_{\text{in}}$ . Intuitively, the less complicate your model is the chance is that you will actually learn instead of memorizing.
- However this doesn't tell you that  $E_{\text{out}}$  will be low. It just says that  $E_{\text{in}}$  and  $E_{\text{out}}$  will be close. That is they can both be terrible but they are closely terrible..

It is impossible to say what is the value for

- One could say it is +1 if the lower left corner is white and -1 otherwise.
- One could say it is +1 if there exist a symmetry axis and -1 otherwise.

Which one is right? Both perform perfectly on the training dataset. The real world problem is not on the training dataset. It is how your hypothesis will perform *out of sample*

Is it possible for us to learn? Short answer is yes. The long answer is Probably Approximately yes. (This is a real mathematical term).

## $E_{\text{in}}$ , $E_{\text{out}}$ , Generalization

To know exactly what we mean by learning, we need to understand the concept of *Generalization*. Generalization is all about how the *in sample* error compare to the *out of sample* error. We define the term error quite simply as the fraction of sample we got wrong. The in sample error is calculated by taking the ratio of the number of sample we got wrong class for it and the total number of sample

## Feasibility of Learning

Learning is trying to find out the target function. The only information we have at the hand is the training data.

Consider the following puzzle.

$$E_{\text{in}} = \frac{\# \text{ of training sample we misclassify}}{\text{Total \# of training sample}} \quad (1)$$

The out of sample is defined similarly.

$$E_{\text{out}} = P(h(x) \neq f(x)) \quad (2)$$

This  $E_{\text{out}}$  is an unknown quantity signifying the probability that the hypothesis( $h$ ) will not match the real target function( $f$ ) in real world.

It is very important that you understand the difference the two. Exercise 1 should give you a very good idea of the difference between the two.

When we got our hypothesis from the learning algorithm, we hope for two things

- $E_{\text{in}}$  is low. This means that our hypothesis performs well at least in the training sample.
- The hypothesis will generalize  $E_{\text{in}} \approx E_{\text{out}}$ . That it will continue to perform well *out of sample*.

Can you tell me what to do so that the chance that  $E_{\text{in}}$  and  $E_{\text{out}}$  match is higher?

Remember when we do pattern recognition we only use  $E_{\text{in}}$  as a guideline.  $E_{\text{out}}$  is the real thing we are trying to make it low.

## Non Linear Transformation

Enough for the theory, now let us go back to practical stuff.

Not all target function is linearly separable. But we can sort of making it more linearly separable by doing a non-linear transformation.

For example, in the figure above, the  $\mathcal{X}$  space on the left is not linearly separable. But, looking at it, we can see that ok the classes has something to do with the distance from teh origin. So,

transforming  $(x_1, x_2)$  to  $\mathcal{Z}$  space might be a good idea. We can do this by just using  $Q : \mathcal{X} \rightarrow \mathcal{Z}$ :

$$Q(\mathbf{x}) = \begin{bmatrix} x_1^2 \\ x_2^2 \end{bmatrix} \quad (3)$$

After we transform our data from  $\mathcal{X}$  space to  $\mathcal{Z}$  space it is clear that we can just use linear perceptron to separate the two.

Your homework is to design a program that does this (and plot it out). This is an excellent programming exercise.

## Noisy Target

In all of the application, your target function is not even deterministic. The same input vector may give you different output. For example, consider the credit card application, someone with the same salary, same sex, same debt and same number of dependent my have entirely different credit behavior.

The target function that we talk about is really target probability (density). The target probability is also a conditional one:  $P(y|\mathbf{x})$ . This reads the probability that the object of input vector  $\mathbf{x}$  will be of class  $y$ . Or concretely the probability that a customer with  $\mathbf{x}$  (salary, debt) would be good customer( $y=+1$ ).

An example of noisy target function is shown below

# 114 Pocket Algorithm

115 So far we have learn Perceptron Learning Algo-  
116 rithm which deals with linearly separable data.

117 If we apply Perceptron Learning Algorithm to  
118 non-linearly separable data. The algorithm will  
119 not stop. (Why?)

120 We can modify this very simply by just keep-  
121 ing(pocketing) the one with the best error rate  
122 as we go. Then we stop after number of iteration  
123 and return the best one we found so far.

124 See exercise.

## 125 Cost Function

126 In pocket algorithm, we choose the hypothesis  
127 with the lowest  $E_{in}$  defined as the fraction of  
128 training data we misclassify.

129 Of course, the final hypothesis must have  
130 something special. But, you may ask is this  $E_{in}$   
131 really the thing we want to minimize?

132 The true answer is depends on the applica-  
133 tion.

134 Let us consider the a fingerprint algorithm.

135 It takes your fingerprints and it tells whether  
136 the customer is in the database or not.

137 There are two customers for this a supermar-  
138 ket and CIA.

## 139 Supermarket

140 The supermarket use fingerprint identification to  
141 give discount to loyal customer. There are 4  
142 things that can happen.

- 143 1. A customer  $\mathbf{x}$  is in the database and the  
144 fingerprint algorithm say that  $\mathbf{x}$  is in the  
145 database.
- 146 2.  $\mathbf{x}$  is **not** in the database but the finger-  
147 print says that [  $\mathbf{x}$  is in the database. This  
148 situation is called *false positive*. But such  
149 situation is not so bad for the supermar-  
150 ket. They just have to give a discount to  
151 another customer. No big deal.
- 152 3.  $\mathbf{x}$  is in the database but the fingerprint  
153 says that  $\mathbf{x}$  is not in the database. This  
154 is called *false negative*. For supermarket,

155 this is quite a big deal since you will em-  
156 barass a loyal customer. We really do not  
157 want this to happen. So we would penalize  
158 this by a lot.

- 159 4.  $\mathbf{x}$  is **not** in the database and the fingerprint  
160 algorithm rejects  $\mathbf{x}$ . This is good. It does  
161 what it is supposed to do.

162 Given the above requirement that we really  
163 don't want false negative. Intuitively, if you make  
164 your algorithm very strict, you will get less false  
165 positive but you will get more false positive vice  
166 versa. It is clear from the requirement that the  
167 false negative and false positive should not be  
168 penalized as equal. The false negative should be  
169 penalize a lot more. So once could construct a  
170 cost function that looks like the following:

171

	Accept	Reject
In the DB	0	1000
Not in the DB	10	0

172  
173  
174

This table can be translated to the the formula

$$E(h) = \frac{1}{N} (1000 \times \# \text{ of false negative} + 10 \times \# \text{ of false positive})$$

175 If we minimize this cost function, will will get  
176  $\approx$  the thing we want.

177 Note that given a fixed training data, the cost  
178 function is a function of hypothesis. Each hy-  
179 pothesis will give you different amount of false  
180 negative an false postive.

## 181 CIA

182 Now let us consider the same fingerprint applica-  
183 tion for CIA agents.

184 When the fingerprint does the right thing.  
185 Good, we like it. But, the real deal is when it  
186 misclassify. There are two ways to misclassify:

- 187 1. False negative.  $\mathbf{x}$  is a CIA agents. He tries  
188 to log into his computer using fingerprint.  
189 The algorithm denies him. No big deal. He  
190 will just try again and if after 10th try it  
191 doesn't work he can just go ask IT dept to  
192 fix it.

193 2. False positive.  $\mathbf{x}$  is not a secret CIA agent 204  
194 but a spy. If the system let the spy in, tons  
195 of information will leak and that is super  
196 bad for the CIA.

197 Given the above requirement, we really  
198 should want to penalize false negative heavily.  
199 One may come up with a cost function that 205  
200 looks something like:

201

	Accept	Reject
In the DB	0	1
Not in the DB	1000	0

202

203

which translate to

$$E(h) = \frac{1}{N} (1 \times \# \text{ of false negative} + 1000 \times \# \text{ of false positive})$$

### 205 Take Home Lesson

206 Cost function is something to minimize to get  
207 what you want so make one up to do what you  
208 need to do.

209 Next week we are going to learning to tell  
210 computer to minimize the cost function.
